What is Classification?

- A bank needs analysis of data in order to learn which loan applicants are safe and which are risky for the bank.
- A marketing manager needs data analysis to help guess whether a customer with a given profile will buy a new computer.
- A medical researcher wants to analyse cancer data in order to predict which one of three specific treatments a patient should receive.
- In each of these examples, the data analysis task is classification, where a model or classifier is constructed to predict categorical labels, such as safe or risky for the loan application data; yes or no for the marketing data; or treatment A, B, or C for the medical data.
- These categories can be represented by discrete values, where the ordering among values has no meaning.

What is Prediction?

- Suppose that the marketing manager would like to predict how much a given customer will spend during a sale.
- This data analysis task is an example of numeric prediction, where the model constructed predicts a continuous-valued function, or ordered value, as opposed to a categorical label.
- This model is a predictor.

How does classification work?

- Data classification is a two-step process: figs 1,2.
- In the first step, a classifier is built describing a predetermined set of data classes or concepts.
- This is the learning step (or training phase), where a classification algorithm builds the classifier by analysing or *learning from* a training set made up of database tuples and their associated class labels.
- A tuple X, is represented by an *n*-dimensional attribute vector $X = (x_1, x_2,...,x_n)$, depicting n measurements made on the tuple from *n* database attributes, respectively $A_1, A_2,...,A_n$.
- Each tuple X, is assumed to belong to a predefined class as determined by another database attribute called the class label attribute.
- The class label attribute is discrete-valued and unordered.
- It is categorical in that each value serves as a category or class.

Data Classification Process

Learning: Training data are analysed by a classification algorithm. Here, the class label attribute is loan decision, and the learned model or classifier is represented in the form of classification rules.

Gini Index Example

How does classification work?

- The tuples in the training set are referred to as training tuples and are selected from the database under analysis.
- In the context of classification, data tuples are samples, examples, instances, data points, or objects.
- Because the class label of each training tuple is provided, this step is also known as supervised learning: the learning of the classifier is supervised in that it is told the class for each training tuple.
- It contrasts with unsupervised learning (or clustering), in which the class label of each training tuple is not known, and the number or set of classes to be learned may not be known in advance.
- This first step of the classification process can also be viewed as the learning of a mapping or function, y = f(X), that can predict the associated class label y of a given tuple X.
- Typically, this mapping is represented in the form of

Data Classification Process

Classification: Test data are used to estimate the accuracy of the classification rules. If acceptable, the rules are used to classify new data.

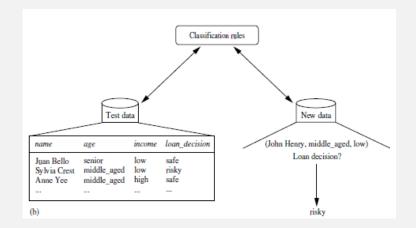

Figure 2: Data Classification

Classification

Bayes Classifiers

Nearest Neighbour Distance Measures Normalisation

Decision Trees

Top Down Induction of Attribute Selection

Attribute Selection Measures

Information Gair Gain Ratio Gini Index

Gini Index Example

What about classification accuracy?

- In the second step (Figure 2), the model is used for classification.
- First, the predictive accuracy of the classifier is estimated.
- If we were to use the training set to measure the accuracy of the classifier, this estimate would likely be optimistic.
- This is because the classifier tends to overfit the data: during learning it may incorporate some particular anomalies of the training data that are not present in the general data set overall.
- Therefore, a test set is used, made up of test tuples and their associated class labels.
- These tuples are randomly selected from the general data set.
- They are independent of the training tuples, meaning that they are not used to construct the classifier.

1.9

Accuracy & Unseen Data

- The accuracy of a classifier on a given test set is the percentage of test set tuples that are correctly classified.
- The associated class label of each test tuple is compared with the learned classifier's class prediction for that tuple.
- If this accuracy is considered acceptable, the classifier can be used to classify future data tuples for which the class label is not known.
- We refer to this as unknown or previously unseen data.
- For example, the classification rules learned in Figure 1 from the analysis of data from previous loan applications can be used to approve or reject new or future loan applicants.

- 1

Numeric Prediction

- Data prediction is a two-step process, similar to that of data classification.
- With prediction, we lose the terminology of class label attribute because the attribute for which values are being predicted is continuous-valued (ordered) rather than categorical (discrete-valued and unordered).
- The attribute is simply the *predicted attribute*.
- Assume we wish to predict the amount that would be "safe" for the bank to loan an applicant.
- The data mining task becomes **prediction**, rather than classification.
- We would replace the categorical attribute "loan decision", with the continuous-valued "loan amount" as the predicted attribute, and build a predictor.

Gini Index Example

Different Models

- Prediction and classification also differ in the methods that are used to build their respective models.
- As with classification, the training set used to build a predictor should not be used to assess its accuracy.
- An independent test set is required.
- The accuracy of a predictor is estimated by computing an *error* based on the *difference* between the **predicted value** and the **actual known value** of y for each of the test tuples X.

. .

Bayes Classifiers

- Classification is the process of **learning a model** that describes different classes of data.
- The classes are predetermined.
- For example, in a banking application, customers who apply for a credit card may be classified as a poor risk, fair risk, or good risk.
- Hence this type of activity is also called supervised learning.

Gini Index
Gini Index Example

Data Models

- Once the model is built, it can be used to classify new data.
- The first step (learning the model) is accomplished by using a training set of data that has already been classified.
- Each record in the training data contains an attribute, called the *class label*, to indicate the class to which the record belongs.
- The model that is produced is usually in the form of a decision tree or a set of rules.

1.1

Building the Model: Issues

- Some of the important issues with regard to the model and the algorithm that produces the model include:
 - the model's ability to predict the correct class of new data;
 - the computational cost associated with the algorithm;
 - and the scalability of the algorithm.

Everyday Classification

- Divide a group of objects so that each one is assigned to one of a number of mutually exhaustive and exclusive categories known as classes.
- Mutually exhaustive and exclusive = assigned to one (only) class.
- Players who play for teams in the same competition.
- Items in the fridge or in the press
- In DCU? Students in CASE4 or SS4.

The Basics

- Utilises probability theory to determine the most likely classification
- Using the 7am Dublin-Cork train, the probability it arrives on-time is between 0 and 1, where 0 is impossible and 1 is certain.
- A probability of 0.7 means that after a long series of observations (N tests), the probability the train arrives on time is 0.7.
- The greater the value of N, the higher your confidence or reliability of your probability.

Multiple Events

A single event does not provide true classification

- Consider again our train example.
- Typically, one would define 4 mutually exclusive and exhaustive events.

Multiple events and their Probabilities P(e)

E1	train cancelled	P(E1)	=0.05
E2	train 10mins or more + late	P(E2)	=0.1
E3	train less than 10mins late	P(E3)	=0.15
E4	train on time	P(E4)	=0.7

1.18

Conditions

- Each of the conditions E1 to E4 must be between 0 and 1
- The sum of all conditions must equal 1.
- P(E1) + P(E2) + P(E3) + P(E4) = 1
- In general, the sum of probabilities of a set of mutually exclusive and exhaustive events must be 1.

Training Sets

- In reality, we cannot measure every single event and instead use a sample (eg. 100 days).
- A Training Set constitutes the results from sample trials that we use to predict the classification of other (unclassified) instances.
- In figure 3, the training set has 20 instances, with 4 attributes and a classification.

Alternate Decision Trees **Attribute Selection**

Measures Information Gair Gain Ratio Gini Index

Gini Index Example

Method 1: Simple

Searching for: {weekday,winter,high,heavy}?

- Look at the frequency of each classification and pick the most common: on time
- The Flaw?
- All unseen instances will be classified in identical fashion
- Not bad, we will be correct 70% (0.7) of the time!
- But the Goal: make correct predictions as often as possible!

Classification

Overview

Nearest Neighbour Distance Measures Normalisation

Decision Trees

Top Down Induction of Attribute Selection

Attribute Selection Measures Information Gain

Gain Ratio Gini Index Gini Index Example

Using Probability: Prior Probability

- This training set contains the classification (E) in addition to 4 other attributes
- Lets assume they are recorded for a reason: they affect the outcome!
- **Definition**. The probability of the train being on time, calculated using the frequency of on time divided by the total instances is known as the prior probability.
- With no other info: P(class = on time) = 14/20 = 0.7
- To effectively use additional attributes, we must introduce conditional probability!

Classification

Overview

Nearest Neighbour Distance Measures Normalisation

Decision Trees

Top Down Induction of Attribute Selection Alternate Decision Tree

Attribute Selection Measures

Information Gair Gain Ratio Gini Index Gini Index Example

Using Probability: Conditional Probability

- What is the probability of the train being on time if the season is Winter?
- In other words: probability that they occur in the same instance?
- Calculation: the number of co-occurrences of on time and Winter divided by the number of occurrences of Winter, ie. 2/6 = 0.33.
- 0.33 is a lot less than 0.7 but it seems intuitive as trains run late, more often, in Winter!

Gini Index Example

Conditional Probability

 Definition. The probability of an event occurring if we know that an attribute has a particular value (or several variables have particular values) is called the conditional probability of the event occurring.

- P(class = on time | season = winter)
- The probability that the class is *on time* **given that** the season is *winter*.

Classification

.

Using Probability: Posterior Probability

- P(class = on time | season = winter) is also called a posterior probability.
- It means that one can calculate for the classification after obtaining the information that the season is Winter.
- By contrast, the prior probability is that estimated before any information is available.

Classification

Attribute Selection Measures

Information Gain
Gain Ratio
Gini Index
Gini Index Example

The Unseen Instance

P(class = on time | day = weekday and season = winter and wind = high and rain = heavy)

- To calculate the most likely classification for the unseen instance given previously we could calculate the probability using the above equation.
- Then also calculate *P* for the other classifications (late, very late, cancelled)
- However, there are only 2 instances with these combinations and thus, unreliable.

Classification

Overview

Bayes Classifiers

Nearest Neighbour
Distance Measures
Normalisation

Decision Trees

Top Down Induction of Decision Trees
Attribute Selection

Attribute Selection Measures

Information Gain
Gain Ratio
Gini Index
Gini Index Example

Method 2: A More Reliable Estimate

Use conditional probabilities based on a single attribute

 $P(class = on time \mid season = winter) = 2/6 = 0.33$

 $P(class = late \mid season = winter) = 1/6 = 0.17$

 $P(class = very late \mid season = winter) = 3/6 = 0.5$

 $P(class = cancelled \mid season = winter) = 0/6 = 0.0$

- As the third P has the largest value, we could conclude that the most likely classification is very late.
- This is a different result to our first approach!
- We could do similar calculations with attributes day, rain and wind.
- This may provide a different result again! Which is best?

Naive Bayes Classifiers

A Means of combining prior probability and conditional probabilities into a single formula

- Strategy: Use this method for each classification in turn and choose the classification with the largest value.
- We invert our previous formula: use the conditional probability that the season is winter given the class is very late.
- P(season = winter | class = very late)

calculated as the **count** of season=winter and class=very late in the **same instance**, divided by the **number of instances** for which the class is very late

Method 3: Using Bayes

Searching for: {weekday,winter,high,heavy}, Using Equation 2

 P(a₁=v₁ | c₁)) means probability it's a weekday given that the class is ontime = 0.64

If we assume the attributes to be independent, the value

 $P(c_i)\times P(a_1=v_1\mid c_i)\times P(a_2=v_2\mid c_i)\times\ldots\times P(a_n=v_n\mid c_i)$

Calculate the **product** for each value of *i* from 1 to *k* and

choose the classification with the largest value.

of this expression can be calculated using the product:

- P(a2=v2 | c1)) means probability it's winter given that the class is ontime = 0.14
- P(a₃=v₃ | c₁)) means probability wind is high given that the class is ontime = 0.29
- P(a4=v4 | c1)) means probability rain is heavy given that the class is ontime = 0.07
- Posterior probability for class = on time: 0.70 x 0.64 x 0.14 x 0.29 x 0.07 = 0.0013

Issues 1

- Note the 4 calculations are not probabilities: they do not add to 1.
- We could normalise so that all values add to 1, but we are only interested in finding the largest value.
- That is what we mean by *posterior probability of* class c...be proportional to...
- Issue: This method works but requires all attributes to be categorical (while some may be continuous)

Alternate Decision Trees

Attribute Selection Measures

Information Gain
Gain Ratio
Gini Index
Gini Index Example

Issues 2

- A second problem is that estimating probabilities by relative frequencies can give a poor estimate if the number of instances with a given attribute/value combination is small.
- In the extreme case where it is zero, the posterior probability will inevitably be calculated as zero.
- This happened for class = cancelled in the above example.
- This problem can be overcome by using a more complicated formula for estimating probabilities . . .

k-NN Classification

- We do not know what the 6 attributes represent but the answer appears obvious!
- We can reasonably predict its classification as negative.
- In practice, there will be many instances in a training set but the same principle applies . . .
- Classification is based on the k nearest neighbours (k is generally small eg. 3 or 5), not just the (single) nearest one.
- This method is known as the k-Nearest Neighbour (or k-NN) classification.

Calculating probability using a 5-NN classifier

- A circle encloses the 5 nearest neighbours of the unseen instance
- There are 3 + signs and 2 signs
- The 5-NN classifier classifies the unseen instance as positive (by 3 to 2)
- This is a 2-dimensional example and with 3 attributes, it becomes a 3 dimensional plane with (x,y,z) points.
- The number of attributes can increase rapidly: difficult to visualise but easily caculated using an algorithm.
- For n attributes, we represent the instances as points (a1,a2,..,an) and (b1,b2,..,bn) in n-dimensional space.

Distance Measures

How do we compute the distance between 2 points?

- Goal: to measure the distance between two instances with n attributes (or in n-space).
- Notation: dist(X,Y) can be used to denote the distance between two points X and Y in n-space.
- There are 3 conditions:
 - The distance of any point from itself is zero: dist(A.A) = 0.
 - The distance from A to B and from B to A are identical: dist(A,B) = dist(B,A)
 - The shortest distance between any 2 points is a straight line.

The Triangle Inequality

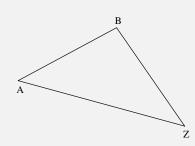

Figure 7: The Triangle Inequality

- The third condition is the triangle inequality.
- It means that the shortest distance between any 2 points is a straight line.
- For any points A,B,Z: dist(A,B) ≤ dist(A,Z) + dist(Z,B)
- Equality occurs only if Z=A or Z=B or Z is on the direct route between A and B.

Euclidean Distance

- We start by illustrating the formula for Euclidean distance in 2-D.
- Assume an instance in the training set to be $u = (a_1, a_2)$ and the unseen instance by $v = (b_1, b_2)$.
- Then the length of the straight line joining the points is:

If $u = (a_1, a_2)$ and $v = (b_1, b_2)$ are two points on the plane, their *Euclidean distance* is given by

$$\sqrt{(a_1-b_1)^2+(a_2-b_2)^2} \tag{3}$$

Euclidean Distance for 3-dimensions

- We can now illustrate the formula for Euclidean distance in 3-D.
- Assume an instance in the training set to be $u = (a_1, a_2, a_3)$ and the unseen instance by $v = (b_1, b_2, b_3)$.

If $u = (a_1, a_2, a_3)$ and $v = (b_1, b_2, b_3)$ are two points in three dimensional space the corresponding formula is

$$\sqrt{(a_1-b_1)^2+(a_2-b_2)^2+(a_3-b_3)^2}.$$

Decision Trees

Top Down Induction of Decision Trees Attribute Selection

Attribute Selection Measures

Information Gain
Gain Ratio
Gini Index
Gini Index Example

Solution

- Normalise all attributes so they run from 0 to 1.
- Assume a range of -8.1 to 94.3. Add 8.1 to all values and range becomes 0 to 102.4. Then divide all by 102.4.
- In general terms, for each attribute *a*, we apply the formula:

$$\frac{a - \min}{\max - \min} \tag{6}$$

If an unseen instance arrives which is outside the range {min,max} it is necessary to calibrate all values again!

Decision Trees

- **Decision tree induction** is the learning of decision trees from class-labeled training tuples.
- A decision tree is a flowchart-like tree structure, where each internal node (non-leaf node) denotes a test on an attribute, each branch represents an outcome of the test, and each leaf node (or terminal node) holds a class label.

Decision Tree Algorithm

- The tree starts as a single node *N*, representing the *training tuples* in *D*.
- If the tuples in *D* are all of the same class, then node *N* becomes a **leaf** and is *labeled* with that **class**.
- Otherwise, the algorithm calls an AttributeSelection method to determine the splitting criterion.
- The splitting criterion tells us which attribute to test at node N by determining the best way to separate or partition the tuples in D into individual classes.
- It also tells us which branches to *grow* from node *N*, determined by the outcomes of the chosen test.
- This splitting attribute may also indicate either a split-point or a splitting subset.

Decision Tree Algorithm: Splitting

- The splitting criterion is determined so resulting partitions at each branch are as *pure* as possible.
- A partition is *pure* if all of its tuples belong to the same class.
- If we split tuples in *D* according to the mutually exclusive outcomes of the splitting criterion, we expect the resulting partitions to be as pure as possible.
- The node *N* is labeled with the splitting criterion, which serves as a test at the node.
- A branch is grown from node N for each outcome of the splitting criterion.
- The tuples in *D* are partitioned accordingly.
- There are 3 possibilities for the splitting attribute A.

3. A is discrete-valued and a binary tree must be produced

- The test at node N is of the form: $A \in S_A$?.
- S_A is the splitting subset for A, returned by AttributeSelection method as part of the splitting criterion.
- It is a subset of the known values of A.
- If a given tuple has value a_j of A and if $a_j \in S_A$, then the test at node N is satisfied.
- Two branches are grown from *N* (Figure 11(c)).
- By convention, the left branch of N is labeled yes so that D₁ corresponds to the subset of class-labeled tuples in D, that satisfy the test.
- The right branch out of N is labeled no so that D₂ corresponds to the subset of class-labeled tuples from D, that do not satisfy the test.

1.65

Terminating Conditions

- The algorithm uses the same process recursively to form a decision tree for tuples at each resulting partition D_i of D.
- The recursive partitioning stops when one of the following terminating conditions is true:
 - All of the tuples in partition D (represented at node N) belong to the same class.
 - 2 There are no remaining attributes on which the tuples may be further partitioned. In this case, majority voting is employed which involves converting node *N* into a leaf and labeling it with the most common class in *D*.
 - There are no tuples for a given branch: a partition D_j is empty.
 In this case, a leaf is created with the majority class in D.
- The goal is to develop classification rules from training set data where a decision tree is formed.

Decision Tree Functions

- Decision trees have two different functions: *data compression* and *prediction*.
- Figure 10 could be regarded as a compact representation of Figure 9.
- Both representations are equivalent: for each of the 14 instances, the given values will lead to identical classifications.
- However, the decision tree can also be used for prediction (for values not in the dataset).
- Would the golfer play if attributes were: {sunny, 74F, 77% humidity, false}?

TDIDT Algorithm

- Decision trees are widely used as a means of generating classification rules because of the existence of a simple but very powerful algorithm called TDIDT, which stands for Top-Down Induction of Decision Trees.
- The method produces decision rules in the implicit form of a decision tree.
- Decision trees are generated by repeatedly splitting on the values of attributes.
- This process is known as recursive partitioning.

1.7

TDIDT Algorithm Rule

- At each non-leaf node an attribute is chosen for splitting.
- This can potentially be any attribute, except that the same attribute must not be chosen twice in the same branch.
- This restriction is innocuous: in the branch corresponding to the incomplete rule
 IF SoftEng = A AND Project = B...
 it is not permitted to choose SoftEng or Project as the next attribute to split on, but as their values are already known there would be no point in doing so.

TDIDT Algorithm: Underspecification

- A major problem with the TDIDT algorithm, which is not apparent at first sight, is that it is underspecified.
- The algorithm specifies 'Select an attribute A to split on' but no method is given for doing this.
- Provided the adequacy condition is satisfied, the algorithm is guaranteed to terminate and any selection of attributes (even random selection) will produce a decision tree, provided that an attribute is never selected twice in the same branch.

1.7

TDIDT Issue: Attribute Selection

- Is under-specification a problem?
- It might be! Many of the decision trees (and the corresponding decision rules) will be of little value for predicting the classification of unseen instances.
- Thus, some methods of selecting attributes may be much more useful than others.
- A good choice of attributes to split on at each stage is crucial to the success of the TDIDT approach.

Football-Netball Tree Analysis (2)

- Figure 18 looks more believable but is it correct?
- Although it is tempting to say that it is, it is best to avoid using terms such as correct and incorrect in this context.
- All we can say is that both decision trees are compatible with the data from which they were generated.
- The only way to know which one gives better results for unseen data is to use them both and compare the results.
- Despite this, it is hard to avoid the belief that Figure 18 is right and Figure 17 is wrong.

Attribute Selection Measures

- An attribute selection measure is a heuristic for selecting the splitting criterion that best separates data partition D of class-labeled training tuples into individual classes.
- If one splits D into smaller partitions according to the outcomes of the splitting criterion, ideally each partition would be pure: all tuples that fall into a given partition belong to the same class.
- Conceptually, the best splitting criterion is the one that most closely results in such a scenario.
- Attribute selection measures are also known as splitting rules because they determine how to split the tuples at a given node.
- The attribute selection measure provides a ranking for each attribute describing the training tuples.
- The attribute having the best score for the measure is chosen as the splitting attribute.

Attribute Selection: ranking attributes

- If the splitting attribute is continuous or if we are restricted to binary trees, then either a split point or a splitting subset (respectively) must also be determined as part of the splitting criterion.
- The tree node created for partition D is labeled with the splitting criterion; branches are grown for each outcome of the criterion; and the tuples are partitioned accordingly.
- We know cover three popular attribute selection measures: information gain, gain ratio, and gini index.

Fundamentals

Let data partition D be a training set of class-labeled tuples.

Assume the class label attribute has m distinct values defining m distinct classes C_i (i = 1,2,..,m). Let $C_{i,D}$ be the set of tuples of class C_i in D. Let |D| and $|C_{i,D}|$ denote the number of tuples in D and $C_{i,D}$ respectively. Classification

Gini Index Example

Information Gain

- Information Gain uses the value or information content of messages.
- Let node *N* represent the tuples of partition *D*.
- The attribute with the *highest* information gain is chosen as the splitting attribute for node *N*.
- This attribute minimizes the information needed to classify the tuples in the resulting partitions and reflects the least randomness or entropy in these partitions.
- Such an approach minimizes the expected number of tests needed to classify a given tuple and guarantees that a simple (but not necessarily the simplest) tree is found.

Information Gain Equation Info(D)

The *expected* information needed to classify a tuple in D is given by:

$$Info(D) = -\sum_{i=1}^{m} p_i \log_2 p_i$$
 (8)

- where p_i is the *probability* that an arbitrary tuple in D belongs to class C_i and is estimated by | C_{i,D}
 |/| D | (countforthatclassdividedbycountfordataset)
- A log function to the base 2 is used because the information is encoded in bits.
- *Info(D)* is just the *average* amount of information needed to identify the class label of a tuple in *D*.

Gini Index Example

Partitioning & Purity

- Assume we must partition the tuples in D on some attribute A having v distinct values {a₁,a₂,..,a_v} as observed from the training data.
- If A is discrete-valued, these values correspond directly to the v outcomes of a test on A.
- Attribute A can be used to split D into v partitions or subsets, {D₁,D₂,..,D_v} where D_j contains those tuples in D that have outcome a_j of A.
- These partitions would correspond to the branches grown from node *N*.
- Ideally, we would like this partitioning to produce an exact classification of the tuples: each partition to be pure!
- However, it is quite likely that the partitions will be impure (e.g., where a partition may contain a collection of tuples from different classes rather than from a single class).

nformation Gain

Gain Ratio
Gini Index
Gini Index Example

Exact Classification

How much more information would we still need (after the partitioning) in order to arrive at an exact classification? This amount is measured by

$$Info_{A}(D) = \sum_{j=1}^{\nu} \frac{\mid D_{j} \mid}{\mid D \mid} \times Info(D_{j})$$
 (9)

- $Info_A(D)$ is the **expected information required** to classify a tuple from D after partitioning by A.
- The smaller the expected information (still) required, the greater the purity of the partition.
- The term $\frac{|D_i|}{|D|}$ acts as the weight of the *j*th partition.

Top Down Induction of Attribute Selection

Attribute Selection Measures

Gain Ratio

Gini Index Gini Index Example

Information Gain: Equation

Information gain is defined as the difference between the original information requirement (based on the proportion of classes) and the new requirement (obtained after partitioning on A). That is:

$$Gain(A) = Info(D) - Info_A(D)$$
 (10)

In other words, Gain (A) tells us how much would be gained by branching on A.

- It is the expected reduction in the information requirement caused by knowing the value of A.
- The attribute A with the highest information gain Gain (A), is chosen as the splitting attribute at node N.

Nearest Neighbour Distance Measures

Normalisation

Decision Trees

Top Down Induction of Attribute Selection

Attribute Selection

Measures

Gain Ratio

Gini Index Gini Index Example

Partitioning by Age

 Using Equation 9 the expected information needed to classify a tuple in D if the tuples are partitioned according to age is

$$Info_{age}(D) = \frac{5}{14} \times \left(-\frac{2}{5}log_2\frac{2}{5} - \frac{3}{5}log_2\frac{3}{5}\right) \\ + \frac{4}{14} \times \left(-\frac{4}{4}log_2\frac{4}{4} - \frac{0}{4}log_2\frac{0}{4}\right) \\ + \frac{5}{14} \times \left(-\frac{3}{5}log_2\frac{3}{5} - \frac{2}{5}log_2\frac{2}{5}\right) \\ = 0.694bits$$

• Thus, the gain in information from this partitioning is:

$$Gain(age) = Info(D) - Info_{age}(D)$$

= 0.94 - 0.69 = 0.246bits

Classification

Attribute Selection Measures

Information Gain

Gain Ratio
Gini Index
Gini Index Example

Gain Ratio

- The Information Gain measure is biased toward tests with many outcomes: it prefers to select attributes having a large number of values.
- For example, consider an attribute that acts as a unique identifier, such as productID.
- A split on productID would result in a large number of partitions (as many as there are values), each one containing a single tuple.
- Because each partition is pure, the information required to classify data set *D* based on this partitioning would be: Info_{productID}(D) = 0
- Therefore, the information gained by partitioning on this attribute is maximal.
- Clearly, such a partitioning is useless for classification.

Gini Index Example

1.

SplitInfo explained

- The SplitInfo value represents the potential information generated by splitting the training data set *D* into *v* partitions, corresponding to the *v* outcomes of a test on attribute *A*.
- For each outcome, it considers the number of tuples having that outcome with respect to the total number of tuples in D.
- It reduces bias towards multi-valued attributes by taking the number and size of branches into account.
- It differs from information gain, which measures the information with respect to classification that is acquired based on the same partitioning.

Normalisation

Decision Trees

Top Down Induction of Decision Trees
Attribute Selection

Attribute Selection Measures

Gain Ratio

Gini Index Example

Gain Ratio is defined as

$$GainRatio(A) = \frac{Gain(A)}{SplitInfo(A)}$$
 (12)

- The attribute with the maximum gain ratio is selected as the splitting attribute.
- Note that as the split information approaches 0, the ratio becomes unstable!
- A constraint is added to avoid this, whereby the information gain of the test selected must be large: at least as great as the average gain over all tests examined.
- Don't use this method if Gain(A) values are small!

Attribute Selection Measures

Information Gain Gain Ratio

Gini Index

Gini Index Example

Binary Split

- The Gini index considers a binary split for each attribute.
- First consider the case where A is a discrete-valued attribute having v distinct values $\{a_1, a_2, ..., a_v\}$ in D.
- To determine the best binary split on A, examine all possible subsets that can be formed using known values of A.
- Each subset S_A , can be considered as a binary test for attribute A of the form: $A \in S_A$?.
- Given a tuple, this test is satisfied if the value of A for the tuple is among the values listed in S_A.
- If A has v possible values, then there are 2^v possible subsets.

Classification

Attribute Selection Measures

Information Gain Gain Ratio

Gini Index

Gini Index Example

Gini Example

- For example, if *income* has three possible values, namely *{low, medium, high}*, then the possible subsets are *{low, medium, high}*, *{low, medium}*, *{low, high}*, *{medium, high}*, *{medium}*, *{high}*, and *{}*.
- We exclude the power set {low, medium, high}, and the empty set from consideration since conceptually, they do not represent a split.
- Therefore, there are 2^{ν} -2 possible ways to form two partitions of the data D, based on a binary split on A.
- When considering a binary split, we compute a weighted sum of the impurity of each resulting partition.

Gini Index Example

Induction of a decision tree using gini index

- Let *D* be the training data in figure 22, where there are 9 tuples belonging to the class *buys computer = yes* and the remaining 5 tuples belong to the class *buys computer = no*.
- A (root) node N is created for the tuples in D.
- We first use Equation 13 for Gini index to compute the impurity of D

$$Gini(D) = 1 - \left(\frac{9}{14}\right)^2 - \left(\frac{5}{14}\right)^2 = 0.459$$

i Index Example

Starting with income

- To find the splitting criterion for the tuples in *D*, compute the Gini index for *each* attribute.
- Start with the attribute *income* and consider each of the possible splitting subsets.
- Consider the subset {low, medium}.
- This would result in 10 tuples in partition D₁ satisfying the condition: *income* ∈ {*low*, *medium*}.
- The remaining 4 tuples of D would be assigned to partition D_2 .

Information Gain Gain Ratio Gini Index

Gini Index Example

Gini Index for income

The Gini index value based on this partitioning is:

$$Gini_{income} \in \{low, medium\}^{(D)}$$

$$= \frac{10}{14}Gini(D_1) + \frac{4}{14}Gini(D_2)$$

$$= \frac{10}{14} \left(1 - \left(\frac{7}{10} \right)^2 - \left(\frac{3}{10} \right)^2 \right) + \frac{4}{14} \left(1 - \left(\frac{2}{4} \right)^2 - \left(\frac{2}{4} \right)^2 \right)$$

$$= \textit{Gini}_{\textit{income}} \in \{\textit{high}\}^{(\textit{D})}$$

Remaining Gini Values

- Similarly, the Gini index values for splits on the remaining subsets are:
 0.458 for the subsets {low, high} and {medium}; and
- 0.450 for the subsets {medium, high} and {low}.
 Therefore, the best binary split for attribute income is on {medium, high} (or {low}) because it minimizes the Gini index (0.459 0.443 = 0.016).
- Evaluating age, we obtain {youth, senior} (or {middle aged}) as the best split for age with a Gini index of 0.357;
 - the attributes *student* and *credit rating* are both binary, with Gini index values of 0.367 and 0.429 respectively.

Information Gain Gain Ratio Gini Index

ini Index Example

Gini selects income

- The attribute *age* and splitting subset {*youth, senior*} therefore give the minimum gini index overall, with a reduction in impurity of 0.459-0.357 = 0.102.
- The binary split age ∈ {youth, senior} results in the maximum reduction in impurity of the tuples in D and is returned as the splitting criterion.
- Node N is labeled with the criterion, two branches are grown from it, and the tuples are partitioned accordingly.
- Both the Gini index and information gain selected age at the root node, but one tree is binary and the other is not.

Conclusions

- Our examination of attribute selection measures is not exhaustive but we focused on the three measures that are commonly used for building decision trees.
- These measures are not without their biases.
 - Information gain is biased toward multivalued attributes.
 - 2 Although the gain ratio adjusts for this bias, it tends to prefer unbalanced splits in which one partition is much smaller than the others.
 - The Gini index is biased toward multivalued attributes and has difficulty when the number of classes is large.
 - It also tends to favor tests that result in equal-sized partitions and purity in both partitions.
- Although biased, these measures give reasonably good results in practice.
